(Dated: February 4, 2011)

An interpretation of the ridge phenomenon found in pp collisions at 7 TeV is given in terms of enhancement of soft partons due to energy loss of semihard jets. A description of ridge formation in nuclear collisions can directly be extended to pp collisions, since hydrodynamics is not used, and azimuthal anisotropy is generated by semihard scattering. The observed ridge structure is then understood as a manifestation of soft-soft transverse correlation induced by semihard partons without long-range longitudinal correlation. Both the p_T and multiplicity dependencies are well reproduced. Some predictions are made about other observables.

I. INTRODUCTION

The observation of ridge structure in two-particle correlation in pp collisions at 7 TeV by the CMS Collaboration at Large Hadron Collider (LHC) [1] has opened up the question of whether it has a similar origin as that already found at Relativistic Heavy-Ion Collider (RHIC) in Au-Au collisions at 0.2 TeV [2–6]. A great deal is known about the ridge in heavy-ion collisions, since various experiments have studied two-particle (with or without trigger) and three-particle correlations. The dominant theme is that the ridge exhibits the effect of high or intermediate-p_T jets on a dense medium. If the phenomenon seen at LHC reveals similar features upon further investigation, it would imply that soft partons of high density can be created in pp collisions and can affect the passage of hard partons through them. If not, a new mechanism needs to be found. Various theoretical speculations have been advanced with varying degrees of attention to the specifics of the CMS data [7–9]. In this article we propose a model that is an extension of our past interpretation of the ridge phenomena in the RHIC data, but is particularly suitable for pp collisions at LHC, since the dynamical origin is jet production rather than hydrodynamics. We have a simple formula that can reproduce the CMS data quantitatively with the use of two parameters that can clearly describe the physics involved.

The most direct approach to the study of ridges is to consider only events selected by triggers with $p_T^{\rm trig}$ in an intermediate p_T range, as first reported by Putschke [3, 10]. The dependence of the ridge yield on centrality in nuclear collisions indicates that the ridge is formed when there is a jet in a dense medium. Having an exponential behavior in $p_T^{\rm assoc}$ at values less than $p_T^{\rm trig}$ suggests that the ridge particles are related to the soft partons, but they have an inverse slope larger than that of the inclusive distribution, implying an enhancement effect of the jet [3, 11]. If triggers are not used as in the study of autocorrelation, ridges are also observed at $|\Delta\eta| > 1$ in central collisions [2, 6]. For pp collisions at LHC we cannot presume the existence of a dense medium of partons, which is a possibility we leave open. However, we can and shall assume that ridge formation is due to high- or intermediate-p_T jets, whether or not the jets are detected by triggers. Our goal is to study the properties of correlation generated by semihard jets. It should be noted that there are models in which the ridge phenomenon can occur without jets, such as in Refs. [9, 12–15].

In the hadronization model based on Refs. [11, 16] the ridge component (due to the recombination of thermal partons) manifests the effect of the semihard parton on the medium. The soft partons have exponential dependence on the transverse momentum k_T, whose inverse slope is T in the absence of semihard partons. For the ridge component the inverse slope is increased to $T' > T$ due to the enhancement of the thermal motion of the soft partons caused by the energy loss of the semihard parton that passes through the medium in the vicinity [17]. That is soft-semihard correlation, which we shall apply to even pp collisions where the notion of thermal partons may be questionable. It is known empirically that there exists an exponential peak at small p_T at LHC [18–20]; that is sufficient for us to refer to the underlying partons as soft, the recombination of which gives the low-p_T hadrons.

In Sec. II we give a short summary of our past work on ridges with emphasis on the distinction between transverse and longitudinal correlations. It is significant to note that the data on ridge reported by PHOBOS [4] do not imply the existence of long-range longitudinal correlation upon closer examination. In Sec. III the transverse correlation is extended to $|\Delta\eta| > 1$ appropriate for CMS measurement. Quantitative analysis of the ridge yield in pp collisions is then carried out in Sec. IV. In the last section we give the conclusion along with some predictions.

II. TRANSVERSE AND LONGITUDINAL CORRELATIONS

Longitudinal correlation has been the primary concern of most theoretical studies on ridges [12–14, 21–23]. The observation by PHOBOS [4] that $|\Delta\eta|$ can be as large as 4 has led to the conclusion that there is empirical evidence for long-range correlation, which is an inherent property of flux-tube models. There are, however, two other aspects about the ridge structure that one should also consider in addition to the large-$\Delta\eta$ aspect of the PHOBOS data. One is A: the property of ridge in the small $\Delta\eta$ limit, and the other is B: the question of how large should $\Delta\eta$ be in order for the correlation to be regarded as long-range. We comment on them in the context of what have been observed at RHIC as a prelude to our discussion about the ridge found at LHC.

A. Transverse Correlation. At midrapidity dihadron correlations in the azimuthal angles have been studied in detail at RHIC; in particular, the dependence of the azimuthal correlation on the trigger angle ϕ_s relative to the reaction plane reveals features that are important about ridge formation [24–27]. Any model on the origin of ridges at $|\Delta\eta| > 1$ should contain properties that are consistent with the azimuthal behavior at $|\Delta\eta| < 1$, since all observed ridge structure have common behavior in $\Delta\phi$ throughout the $\Delta\eta$ range. The ridge yield as a function of ϕ_s has been studied in a model where the angular correlation between the trigger and local flow direction is limited [28]. It is found that a Gaussian width of $\sigma \sim 0.34$ can reproduce the data [24, 26, 27]. The model suggests that thermal activities of the soft partons in the vicinity of the trajectory of the semihard parton (i.e., within a cone of angular range of σ) are enhanced by the energy loss of the latter to the medium. Those enhanced thermal partons hadronize into the ridge particles that rise above the background. That is transverse correlation between the soft and semihard partons, the only type that can be studied when $|\Delta\eta|$ is restricted to < 1. After finding satisfactory explanation of the azimuthal correlation in the data this way for triggered events, the natural question to follow is how such correlation influences the single-particle distribution when triggers are not used. Semihard partons can be pervasive if their k_T is around 3 GeV/c or lower. It is found that the semihard-soft transverse correlation can give rise to a significant azimuthal anisotropy [17, 29], and that $v_2(p_T, N_{\rm part})$ can be quantitatively reproduced as a consequence of the ridge effect in inclusive distribution [30]. This will become a key input in our discussion below where the nature of the transverse correlation will be made explicit.

B. Longitudinal Correlation. At first sight of the PHOBOS data on the $\Delta\eta$ range of the ridge distribution [4], anyone having some familiarity with multiparticle production is likely to regard $|\eta_2 - \eta_1| \sim 4$ as indicative of long-range correlation between the trigger at η_1 and ridge particle at η_2. However, to quantify the notion of correlation range it is important to compare it to the η-range of the single-particle distribution. A recent study shows that the ridge distribution in $\Delta\eta$, denoted by $dN_R^{ch}/d\Delta\eta$, can be related empirically to the single-particle distribution, $dN^{ch}/d\eta$, by using the two relevant sets of PHOBOS data only [4, 31] without any theoretical input [32]. That phenomenological relationship

$$\frac{dN_R^{ch}}{d\Delta\eta} \propto \int_0^{1.5} d\eta_1 \left.\frac{dN^{ch}}{d\eta_2}\right|_{\eta_2=\eta_1+\Delta\eta} \tag{1}$$

involves a shift in η_2 of the charge hadron and an integration over the trigger η_1, and shows that the range of correlation in $\Delta\eta$ is no more than the range of the inclusive distribution apart from the smearing of the trigger acceptance, which lengthens the $\Delta\eta$ range by 1.5. The implication is that there is no long-range longitudinal correlation. Any successful model of ridge formation should be able to explain the simple relationship shown in Eq. (1). In Ref. [32] an interpretation of that relationship is given in terms of transverse correlation that we discuss in more detail in the next section.

III. RIDGE AT $|\Delta\eta| > 1$

The phenomenological verification of Eq. (1) directs one's attention to the origin of ridge formation without intrinsic longitudinal correlation at large $\Delta\eta$. From all that have been learned experimentally about the ridges, there is no indication that such structure can be found in the absence of any jet. Even in autocorrelation studies where no triggers are used, ridges are found in the kinematical region where minijets are detected [2]. Our approach is therefore to start with jet-induced transverse correlation at $|\Delta\eta| < 1$ and to extend it to larger η separation, in contrast to other studies where long-range longitudinal correlation at low p_T exists without jets and then a large-p_T parton is introduced to define the $\Delta\eta$ range. The approach we adopt was actually advocated even before the discovery of ridge was reported by Putschke [10] at a time when the phenomenon was regarded as the pedestal lying under the jet peak [33, 34]. Now, with more data and model analyses of the transverse correlation at hand, the extension to large $\Delta\eta$ can be done with more definiteness.

To be more specific, let us consider the ridge found by CMS at LHC, where only charged particles with $|\eta| < 2.4$ and $p_T < 4$ GeV/c are used in the analysis. In that acceptance region the hadron p_L is less than 22 GeV/c, so Feynman x_F is $< 6.3 \times 10^{-3}$ at $\sqrt{s} = 7$ TeV, and the corresponding partons that recombine have even lower x values. Those are soft wee partons deep in the sea, whose correlations can be strongly influenced by fluctuations. Suppose that a semihard scattering occurs in a pp collision at 7 TeV and sends a parton to the $\eta \approx 0$ region with a parton momentum k_T in the 5-10 GeV/c range, which we shall regard as intermediate at LHC. Whatever the medium effect on it may be, it can lead to a cluster

of hadrons with limited range in η and ϕ [1]. It cannot directly cause the production of an associated particle at $\eta = 2.4$ since the p_L of that particle can exceed 20 GeV/c, hence forbidden by energy conservation. Any particle produced outside the jet peak carries longitudinal momentum that is driven by the initial partons (right- or left-movers) of the incident protons. In the conventional parton model it is assumed that there are no significant longitudinal constraints on those initial partons [35, 36]. We add, however, that their transverse momentum distribution can be affected by the semihard scattering before they recede from one another. At early time the right- and left-movers need not be arranged as in Hubble expansion, i.e., a right-moving parton may be located on the left side of the region of uncertainty, and vice-versa; hence, those initial partons can be sensitive the passage of the semi-hard parton across their ways. The quantum fluctuations that generate the transverse k_T distribution of the forward (or backward) moving partons may be enhanced by the energy loss of the semihard parton. More specifically, let $\exp(-k_T/T)$ represent the k_T distribution in the absence of semihard scattering; then our assertion is that the distribution changes to $\exp(-k_T/T')$ with $T' > T$ in the presence of semihard scattering, provided that the affected partons are in the vicinity of the semihard parton trajectory in the transverse plane, i.e., $\Delta\phi$ is limited on the near side. Furthermore, such a change occurs for all partons independent of their longitudinal momenta up to $x \sim 10^{-2}$, say. This enhancement is in essence the transverse correlation discussed in Sec. II.A, but now the semihard parton at $\eta \approx 0$ induces a change in the transverse distribution of the soft partons from T to T' at all η in the limited region $|\eta| < 2.4$ under study.

The CMS experiment does not identify any particle as the trigger, so the pseudorapidity of the semihard parton cannot be specified. All charged particles accepted in the window $|\eta| < 2.4$ are used for the analysis of the two-particle correlation. Thus the correlated particles may be at $\eta_{1,2} = \pm 2.4$, resulting in $|\Delta\eta| = |\eta_1 - \eta_2|$ as large as 4.8. Hereafter, η_1 and η_2 do not refer to trigger and associated particles, respectively, but to any two particles whose correlation is measured by CMS. The semihard parton may be anywhere in between ± 2.4. The huge jet peak observed in Ref. [1] corresponds to particles that are produced by thermal-shower recombination and therefore must be close in η to the semihard parton, but the peak distribution in $\Delta\eta$ does not indicate where it is. The flat ridge distribution that lies below the jet peak only reveals the response of the medium in terms of enhanced thermal partons without any information about the locations of the shower partons. The ridge particles have transverse distribution that is characterized by the same inverse slope T' as for the enhanced soft partons. That is a property of recombination [16, 30]. No explicit longitudinal correlation has been put in.

In order to describe pion and proton production in the same formalism of recombination of thermal partons at low p_T, it is shown that the replacement of p_T by E_T, where $E(p_T) = (m_h^2 + p_T^2)^{1/2} - m_h, h = \pi$ or p, is sufficient to account for the mass effect and that the inclusive ridge distribution can reproduce $v_2^h(E_T, N_{part})$ at low E_T [30]. Being the difference between the enhanced distribution and the background, that ridge distribution is

$$R(p_T) = R_0(e^{-E_T/T'} - e^{-E_T/T}) \tag{2}$$

for nuclear collisions. It is the soft response to the semihard partons. We will apply the same description to pp collision below. The difference $\Delta T = T' - T$ is a measure of the magnitude of the influence by semihard scattering without which there is no ridge.

IV. RIDGE YIELD IN pp COLLISION AT LHC

We now focus on the ridge yield measured by CMS. Let the single-particle distribution be $\rho(p_T, \eta) = dN/p_T d\eta dp_T$, which will be abbreviated by $\rho_1(i)$ for the ith particle, so that two-particle distribution is denoted by $\rho_2(1, 2)$. Define two-particle correlation by $C_2(1, 2) = \rho_2(1, 2) - \rho_1(1)\rho_1(2)$. The measure for ridge used by CMS is

$$\mathcal{R}_{\rm CMS}(1, 2) = NC_2(1, 2)/\rho_1(1)\rho_1(2), \tag{3}$$

where N is the number of charged particles in a multiplicity bin. In more detail the quantities in Eq. (3) are averaged over bins of p_T, so Ref. [1] exhibits

$$\mathcal{R}_{\rm CMS}(p_T, \Delta\eta, \Delta\phi) = N \frac{\prod_{i=1,2} \left[\int_{[p_T]} dp_{Ti} p_{Ti}\right] C_2(1, 2)}{\prod_{i=1,2} \left[\int_{[p_T]} dp_{Ti} p_{Ti} \rho_1(i)\right]} \tag{4}$$

where $[p_T]$ denotes the range of integration from $p_T - 0.5$ to $p_T + 0.5$ (GeV/c). A ridge then appears in the 2D $\Delta\eta$-$\Delta\phi$ distribution. A projection of it onto $\Delta\phi$ is done by integrating $|\Delta\eta|$ over the range 2.0 to 4.8. The associated yield in the ridge is then determined by integrating over a range of $\Delta\phi$ around 0 where $\mathcal{R}_{\rm CMS}$ is above its minimum, i.e.,

$$Y_R(p_T, N) = \int_R d\Delta\phi \int_{\pm 2}^{\pm 4.8} d\Delta\eta \; \mathcal{R}_{\rm CMS}(p_T, \Delta\eta, \Delta\phi). \tag{5}$$

This measure of the ridge yield is given for 4 bins of p_T and N each [1]. The data points are shown in Fig. 1.

What is remarkable about the data is that Y_R is very small for both $0.1 < p_T < 1$ and $3 < p_T < 4$ GeV/c, but jumps up by nearly an order of magnitude in the $1 < p_T < 2$ GeV/c bin. It is very unusual in high-energy physics where the p_T behavior is so drastically different on the two sides of 1 GeV/c. The increase of Y_R with N is not surprising, especially if one has in mind that jets are connected with the ridge phenomenon.

Our explanation of the p_T and N dependencies of Y_R is very simple, based on what has already been discussed. We assume no longitudinal correlation, as in [32], which

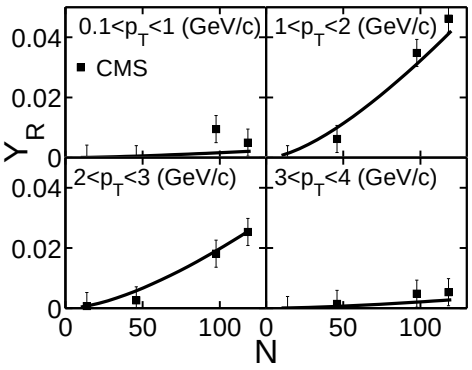

FIG. 1: Ridge yield vs multiplicity N for 4 bins of p_T. Data are from Ref. [1], and lines are from model calculation.

can explain the PHOBOS data [4]. Thus the only contribution to $C_2(1,2)$ is from transverse correlation that gives rise to the ridge distribution given in Eq. (2) as an η-independent response to the semihard jet at any η_{jet}. We therefore write

$$C_2(1,2) = R(1)R(2). \tag{6}$$

This is a very unconventional description of correlation that we are proposing, since one usually expects an unfactorizable form for correlation. The two particles at η_1 and η_2 are correlated because their p_T distributions are both enhanced by the jet. $R(1)$ and $R(2)$ are independent responses, so they enter into $C_2(1,2)$ as factorized products. We emphasize that Eq. (6) is a correlation between two soft particles, each of which being correlated transversely to the unobserved jet as described by Eq. (2). An analogy for this is the adage that rising tide raises all boats — even though, we add, there are no intrinsic horizontal correlations among the boats. Putting Eq. (6) in (4) and (5) we obtain

$$Y_R(p_T,N) = cN \prod_{i=1}^{2} \left[\frac{\int_{[p_T]} dp_{Ti} p_{Ti} R(p_{Ti},N)}{\int_{[p_T]} dp_{Ti} p_{Ti} \rho_1(p_{Ti})} \right], \tag{7}$$

where c is an adjustable parameter that depends on the experiment. This is an explicit formula that enables us to do phenomenological analysis.

The single-particle distribution for $|\eta| < 2.4$ at 7 TeV is given by CMS in the Tsallis parametrization [19]

$$\rho_1(p_T) = \rho_0 (1 + \frac{E_T}{nT_0})^{-n} \tag{8}$$

with $T_0 = 0.145$ GeV/c and $n = 6.6$. The average p_T found from the above fit is $\langle p_T \rangle = 0.545$ GeV/c.

We use Eq. (8) in (7) and fit the data in Fig. 1 with two parameters (apart from normalization), which we choose to be T and β, where

$$\frac{\Delta T}{T} = \beta \ln N, \qquad \Delta T = T' - T. \tag{9}$$

This dependence on N is reasonable, since at higher N there is higher probability for jet production and hence larger ΔT, which is in the exponent in Eq. (2). The result of the fit is shown by the solid lines in Fig. 1 for

$$T = 0.294 \text{ GeV} \qquad \text{and} \qquad \beta = 0.0175. \tag{10}$$

Evidently, our model reproduces the data very well for all p_T and N bins. $Y_R(p_T,N)$ is small at small p_T because $R(p_T)$ in Eq. (2) is suppressed as $p_T \to 0$. The reason for that is discussed below. $Y_R(p_T,N)$ is also small at large p_T; that is due both to the exponential suppression of $R(p_T)$ and the power-law decrease of $\rho_1(p_T)$ at high p_T. The increase with N that is most pronounced in the $1 < p_T < 2$ GeV/c bin, where $R(p_T)$ is maximum, is clearly due to the enhancement of T when jet production is more likely in accordance to Eq. (9). At $N = 100$, $\Delta T/T$ is about 8%, which is slightly lower than that observed in nuclear collisions at RHIC where $T = 355 \pm 6$ MeV/c and $T' = 416 \pm 22$ MeV/c for $4 < p_T^{\rm trig} < 6$ GeV/c [3].

The reason why $R(p_T)$ must vanish as $p_T \to 0$ is related to azimuthal anisotropy in nuclear collisions. We have advocated the view that the ridge component before being averaged over ϕ contains all the ϕ dependence of the inclusive distribution [17, 37]. In that approach which has been worked out in more detail recently in [30], it is shown without using hydrodynamics that v_2 (referred to as elliptic flow in hydro description) can be reproduced at all centralities, provided that $R(p_T) \to 0$ at vanishing p_T because $v_2(p_T) \to 0$. Since the azimuthal behavior is determined primarily by the initial geometry of the collision system [17, 29, 37], such an approach may well be applicable to pp collisions, for which the validity of hydrodynamics used for nuclear collisions is doubtful. The origin of the ϕ dependence in the geometrical approach is the anisotropy of semihard emission when the initial configuration is almond-shaped. Similarly, it is reasonable to consider the initial configuration in pp collisions also, when the impact parameter is non-zero, and we expect significant ϕ anisotropy in the produced particles.

The Tsallis distribution in Eq. (8) has the property of a power-law behavior at large p_T, but an exponential behavior, $\exp(-E_T/T_0)$, at low p_T. It is then of interest to note the difference between the values of T_0 and T, the latter being twice larger than the former. It may appear as being inconsistent; however, the average $\langle p_T \rangle$ of $\exp(-E_T/T)$ is 0.6 GeV/c, only 10% higher than that for Eq. (8). Thus different parametrizations of the E_T distribution give essentially the same physical quantity. Eq. (8) is a fit of the CMS data [19] that emphasizes the p_T^{-n} behavior at high p_T, while Eq. (2) is a theoretical model of the ridge distribution at low p_T.

V. CONCLUSION

We have given an interpretation of the ridge phenomenon in pp collisions in terms of soft partons on which very little is known. By drawing on what we do know

about the soft partons in nuclear collisions, we are led to the implication that a dense medium can be created even in pp collisions at 7 TeV. The primary input in our approach to explaining the observed ridge yield is the assertion that the correlation is of the factorizable form $R(1)R(2)$, where $R(i)$ is the response of the ith soft particle to the unobserved jet, so that two independent transverse correlations of the semihard-soft type can lead to a net soft-soft correlation in $C_2(1,2)$.

The success of our approach applied to pp collisions at 7 TeV suggests that (a) the medium can be responsive to semihard jets, (b) there can be azimuthal anisotropy, (c) the p_T spectrum in the ridge is harder than that of the inclusive, and (d) that hadronization is by recombination. None of the above rely on the validity of hydrodynamics for pp collisions, or the existence of intrinsic long-range longitudinal correlation, and all of them can be checked by further experimental measurements. The last item cannot be checked directly, but one of its consequences is that the p/π ratio can be large, which is a property of all recombination/coalescence models [39]. We expect the p/π ratio in the ridge to increase with p_T at low p_T in pp collisions at 7 TeV, although the rate of that increase depends on the soft parton density, on which we have insufficient knowledge to predict. A ratio larger than 0.2 cannot be explained by fragmentation. Thus the experimental determination of the p/π ratio in the ridge will be very interesting and should provide further insight on the structure and origin of the ridge.

The basic issue that the observation of a ridge by CMS has opened up is whether a system of high density soft partons can be created in pp collisions. The system may be too small for the applicability of hydrodynamics, but azimuthal anisotropy can nevertheless exist for small systems in non-central collisions, so consequences on ϕ asymmetry should be measurable, as the ridge structure on the near side demonstrates. Our consideration of ridge formation as being generated by semihard jets applies to both hadronic and nuclear collisions. Thus we go further to suggest that even in single-particle distribution in pp collisions at LHC there may exist a ridge component that contains all the ϕ dependence, as found in Au-Au collisions [17, 29, 30].
